

Reasoning about Z specifications

A primary purpose of formal specification methods is to be able to make deductions about the behavior of any implementation that realizes a formal Z specification. In this episode, we will examine an example of reasoning from a Z specification. In particular, we explore a significant aspect of the coherence (i.e., consistency) of Z specifications.

One thing we certainly wish to be confident about a specification is that a state invariant actually *is* invariant. That is, for each \square operation, we should be able to deduce from the pre/post-conditions that if the invariant is true before the operation is performed, it is still true after the operation is performed. For our first instance of proving from a Z specification, we shall again refer to Diller's telephone database example. We will not formally establish the invariant for all operations, but will explore a couple of instances.

The first operation schema we pursue is AddEntry. We prove that

$$\text{AddEntry } \square \text{ dom telephones } \square \text{ members } \square \text{ dom telephones}' \square \text{ members}'.$$

The first step is to expand the schema into the appropriate logical formulas to obtain

$$\begin{aligned} & (\text{name? } \square \text{ members} \\ & \quad \square \text{name? } \mid \square \text{ newnumber? } \square \text{ telephones} \\ & \quad \square \text{ telephones}' = \text{telephones } \square \{ \text{name? } \mid \square \text{ newnumber?} \} \\ & \quad \square \text{ members}' = \text{members}) \\ & \square \text{ dom telephones } \square \text{ members} \\ & \square \text{ dom telephones}' \square \text{ members}'. \end{aligned}$$

The implication follows in four simple steps.

$$\begin{aligned} & \text{dom telephones}' \\ & = \text{dom telephones } \square \{ \text{name?} \}, \text{ since } \text{telephones}' = \text{telephones} \\ & \quad \square \{ \text{name? } \mid \square \text{ newnumber?} \} \\ & \square \text{ members } \square \{ \text{name?} \}, \text{ since } \text{dom telephones } \square \text{ members} \\ & = \text{members}, \quad \text{since } \text{name? } \square \text{ members} \\ & = \text{members}', \quad \text{since } \text{members}' = \text{members}. \end{aligned}$$

Next we examine the state invariant for an apparently more interesting case, the RemoveMember schema — this schema changes *both* state variables.

We prove that

RemoveMember \sqsubseteq dom telephones \sqsubseteq members \sqsubseteq dom telephones' \sqsubseteq members'.

Again, the first step is to expand the schema into the appropriate logic formulas to obtain

(name? \sqsubseteq members
 \sqsubseteq members' = members \setminus {name?}
 \sqsubseteq telephones' = {name?} \llcorner telephones)
 \sqsubseteq dom telephones \sqsubseteq members
 \sqsubseteq dom telephones' \sqsubseteq members'.

This is easily proven by

dom telephones'
= dom telephones \setminus {name?} since telephones' = {name?} \llcorner telephones)
 \sqsubseteq members \setminus {name?} since dom telephones \sqsubseteq members
= members'.

Proofs of the state invariant for the other \sqsubseteq operation schemas are similar. Internal inconsistency is a fatal flaw for a formal specification, but may be difficult to detect. Verifying that the written operation specifications logically imply all invariants are preserved is therefore a useful check to perform.
